Project PAALM: Phalangeal Angle Approximation through the Leap Motion Controller

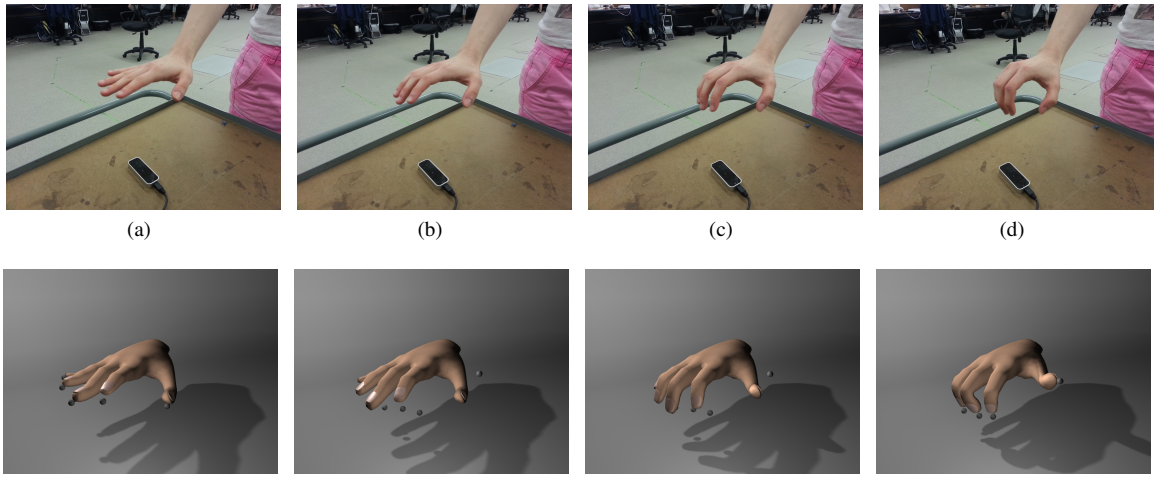

Figure 1: *Top Left to Right: The Leap Motion controller tracks to palm and fingers above it. Bottom Left to Right: Our PAALM system estimates finger positions in real-time based on the Leap input. The bottom animation was created using a Maya plugin which communicates directly with the device to create keyframes for a hand model which correspond to the live input.*

Abstract

Hands are fundamental in a variety of domains including character animation, sign language, robotics, and gestural user interfaces. However, the dexterity and flexibility of the hand make it difficult to accurately capture information about complex gestures. Current approaches are expensive, restrict movement of the hand, confine the user to a capture region, or require time-consuming manual cleanup. Thus, we investigate the use of a fast, approximate, and inexpensive method for obtaining the phalangeal joint angles of the hand using the Leap Motion Controller [Leap Motion 2013]. Our framework directly integrates the Leap Motion controller into Maya to create an intuitive user interface for animating hand motions.

1 Introduction

Hands are fundamental in a variety of domains including character animation, sign language, robotics, and gestural user interfaces. Hands are both the primary mechanism we use to interface with the physical world as well as an important component for communication. In computer graphics, the realistic animation of the human hand is a long-standing and difficult problem [Zhao et al. 2012] because our hands are very dexterous and versatile. Detailed and subtle finger motions and hand movements help bring characters to life but are often difficult to capture. Much research has been devoted to efficiently capturing hand gestures, using imaged-based, glove-based, and marker-based techniques. However, most existing methods remain expensive, can restrict the motion of the hand, might confine the user to a space, or require time-consuming manual cleanup. For example, dexterous finger motions are very difficult to capture with optical, marker-based systems because markers frequently become occluded and the proximity of the fingers cause automatic labeling algorithms to frequently mislabel markers. Conversely, solutions involving wearable measurement devices, such as cybergloves, are often bulky and restrict delicate movements.

Thus, we investigate an effective method for approximating phalangeal joint angles of the hand that is portable, unrestrictive, real-time and cost-effective. Our approach utilizes a new and unexplored technology called the Leap Motion Controller that is roughly the size of a flash drive and tracks individual finger movements to 1/100th of a millimeter [Leap Motion 2013]. This device is designed to sit on a desk and plugged into a PC via USB. Internally, the device tracks finger motions in a one meter hemispherical area above the device using two cameras and three infrared LEDs.

Our framework implements an application programming interface (API) for obtaining and visualizing the phalangeal joint angle data using the Leap Motion Controller which is suitable for direct import (via a plug-in) into a rigged Maya hand model. unlike a purely image-based system, the Leap Motion device does not require one to process raw images, but instead provides users with direction vectors and projected lengths for each finger as well as an orientation for the palm. We map this output from the Leap Motion controller to IK targets for each finger and specify joint limits enforce natural finger movements.

Our main contributions are as follows:

- An portable, cost-effective, real-time, and freehand method of obtaining phalangeal joint angles using an unexplored technology.
- An application programming interface (API) for obtaining and visualizing the phalangeal joint angle data using the Leap Motion Controller which is suitable for direct import (via a plug-in) into a rigged Maya hand model.

2 Related Work

Recording hands remains a difficult problem and researchers have investigated numerous ways to acquire hand gestures.

2.1 Marker-based Systems

Marker-based motion capture systems are a popular means of obtaining hand motion data. The standard approach requires attaching approximately 30 retro-reflective markers to the hand and tracking them over time [Vicon 2013]. The temporal data is then used to reconstruct a 3D representation of the hand and its motions. Recent advancements in hand motion capture have made it possible to achieve descriptive hand motion data with a reduction in the number of markers [Hovet et al. 2012]. Though even with such advancements, marker-based approaches still pose significant problems in hand motion detection. Gestures featuring self-occlusion (fingers overlapping one another) are difficult to detect using the system. Automatic marker tracking is not effective in maintaining the markers over time. Thus, the process of tracking markers is then a tedious one, requiring manual labeling that is both time-consuming and error prone [Zhao et al. 2012].

2.2 Glove-based Systems

Glove-based systems such as the CyberGlove [Cyberglove 2013] provide a useful method of obtaining hand gesture data that is free from issues that arise when fingers occlude each other. Such systems have been used for the recognition of sign language [Vogler and Metaxas 2003]. The motions recorded using the system, however, are often noisy and fail to capture delicate articulations with high precision [Zhao et al. 2012]. Likewise, the system restricts the natural motion of the hand, making capturing realistic gestures a more complex task. The advantage of using the Leap Motion Controller for our approach is that it permits the hand to move freely and naturally.

2.3 Image-based Systems

Computer vision has offered a promising alternative to data gloves and other worn mechanisms for detecting hand motions [Erol et al. 2007]. Image-based systems have been shown to support the acquisition of natural hand movements and offer a less expensive approach to marker-based systems.

[Martin de La Gorce 2011] tracked hand poses based on monocular video using a model of temporal continuity to handle occlusions. Other image-based techniques rely on hand motion priors stored in a large database to aid capture [Wu et al. 2001; Zhou and Huang 2003; Wang and Popovic 2009; Romero et al. 2010]. However, these approaches rely on having a large hand database to guide pose recognition and generation and thus have the drawbacks of requiring a large number of pre-collected poses and thus whose recognition is restricted to poses similar to those in the database. In an other approach, [Oikonomidis et al. 2011] enhanced the accuracy of imaged-based techniques through the use of a RGB-depth camera. A recent device called Digits has been developed that uses a wrist-worn gloveless sensor to detect 3D hand gestures [Kim et al. 2012]. The sensor features two infrared illumination schemes that are used to produce a hand model through inverse kinematics. The wrist-worn device avoids the need for any embedded sensors in the environment and permits the hand to move freely as well as the user to move about without being confined to a capturing region. Vision-based techniques have the drawbacks of being computationally expensive, noisy and vunerable to a lack of obvious features on the hand and occlusions.

2.4 Hybrid Systems

A recent innovation has been combining marker-based and image-based systems to provide higher fidelity hand motion data [Zhao et al. 2012]. These systems are capable of accurately detecting hand motions even in cases of selfocclusion. The markers are used as reference when rebuilding hand motion data using an RGB-depth camera such as the Microsoft Kinect. These systems are robust and do not significantly restrict hand movements as the markers are small. The potential shortcomings of this system is that it still requires an expensive, non-portable optical motion capture system to capture the markers and must run a computationally expensive optimization to solve for hand positions which saistify both the RGB-D image and the marker positions.

3 LEAP

The Leap Motion Controller offers a cost-effective, fast and precise means of capturing live hand motion data. This device is small (3x1x0.5 inches), designed to sit on a desk and plugged into a PC via USB. Thus, it is extremely portable and lightweight.

The Leap Motion Controller is an infrared-based device, featuring three infrared LEDs and two light sensors. The device is capable of tracking position changes as small as a 1/100th of a millimeter within a detection region of eight cubic feet. Its sensors capture spatial information at 290 frames per second and provide data about the tip position, tip velocity, length, direction, and width of pointable

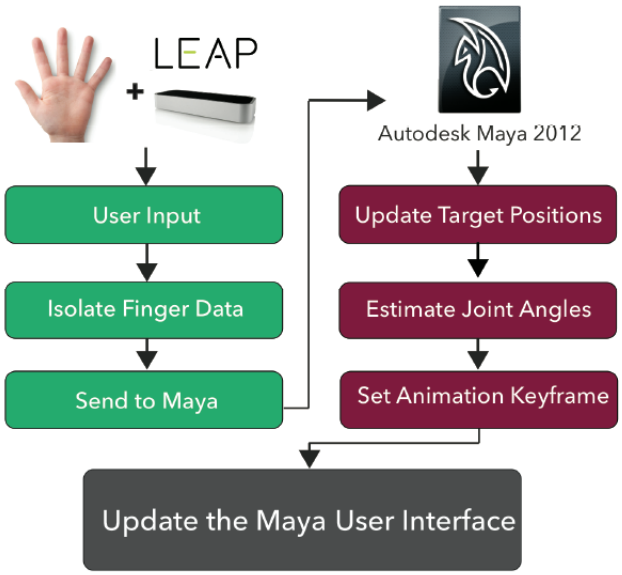

Figure 4: *PAALM Overview*

objects, such as a pen or a finger, in 3D space.

With respect to fingers, the device can determine to which hand a set of fingers belong and provide details about a hand's palm position and normal (Figure 2). Additionally, the hand data includes a palm sphere radius, or the radius of a spherical object that could be held within the palm of the hand. A small radius suggests a closed hand while a large radius suggests an open hand with fingers spread further apart (Figure 3). Occluded fingers are not detected by the device, so crossed or folded fingers will disappear from the output data until they are detected again.

All of the data provided by the Leap Motion Controller is organized into individual frames which can be accessed and manipulated using the device's application programming interface.

4 Approach

In this section, we discuss how we map the output from the LEAP device to a rigged model in Maya. The device API provides unordered direction vectors whose lengths correspond to the length of each finger seen by the device. The device omits information for any fingers it fails to detect, such as fingers folded into the palm or crossed together. The size, position, and orientation of the palm is also provided by the Leap API.

Thus, inferring hand positions from the Leap input requires mapping these direction vectors to the finger and palm of our model. The main insight of our approach is to use the detected lengths combined with apriori information regarding the range of motion for each finger joint to determine IK targets for each finger. The result is that the metacarpal-phalangeal joint (the finger joint closest to the palm) has the orientation as the direction vector whereas the amount of bend in the phalangeal joints is estimated by the length of the vector. The palm orientation and position is mapped similarly to the root of hand model.

For this straighforward approach to work, we must first calibrate our system for the finger sizes of the capture subject, which can differ greatly between individuals. During this step, our capture subject only need hold their hand above the leap device in a rest pose with open palm and spread fingers, such that the device can detect the entire hand. We then record the detected length of each finger over 1000 frames (approximately 10 seconds) and use the average of the recorded lengths as the standard for comparison in all subsequently captured frames. We compute a length ratio for each finger by dividing the finger's current length by its associated standard length.

Lastly, we must account for two complicating factors: one, the finger data for a hand received from the Leap Motion Controller is not guaranteed to be ordered; and two, some number of fingers might not be detected at all. The first problem is solved with a heuristic where we sort the finger data by x-coordinates in 3D space (chosen because it matches the orientation of a detected hand in the device's coordinate space). We use the right hand in our demos. The system is suitable for either hand or can support two hands if they are not stacked on top of each other; however, the configuration requires that this be specified during calibration. The sorted fingers receive unique identifiers that are used to associate standard lengths (acquired during calibration) with lengths from subsequent frame updates. We deal with the second problem using a simple temporal heuristics that stop tracking a finger once it disappears. Thus, we assume that fingers stay in the same position until the Leap device sees it again.

5 Results

Our framework has two main components: a Python script for interfacing with the Leap Motion Controller and a Maya plug-in written in PyMel for animating hand motions.

As described in the previous section, we obtain the direction vector, length ratio, and identifier of each finger from the Leap device, which we then map to a rigged model using a Maya plug-in.

Communication with the Maya plug-in is socket-based, occurring through Maya's command port. The plug-in features a script that receives all of the direction, length ratio, and identifier data for each Leap-detected finger. The identifiers associate the direction and length ratio for each Leap-detected finger with a chain of joints in Maya. We designate each joint chain as a Maya-finger.

Each Maya-finger is initialized with a length based on the joint positions in the finger's joint chain. The length is obtained through the summation of the vector magnitudes between a joint and its succeeding joint for every joint in a Maya-finger. The Maya-finger is assigned a target sphere that designates a point in 3D space for use with inverse kinematics.

The Maya plug-in processes the finger data by selecting a Maya-finger that corresponds to a unique identifier provided by a Leap-finger. The correspondence between two fingers permits us to map input user hand motions to target positions in Maya. For each Leap-finger, we normalize the direction vector and multiply it by the length ratio. The product is a direction vector with a length scaled to approximate the bend of the fingers detected by the Leap. We multiply the scaled direction vector by the length of the Maya-finger to map this direction vector to the Maya coordinate space with respect to the Maya-finger.

A new target position for the Maya-finger is computed by adding the scaled direction vector to the base position of the Maya-finger. The base position is designated by the first joint in the Maya-finger's joint chain. We use the position of the knuckle joint for each finger as the base position. We set the position of the target sphere to be this new target position and perform IK to approximate new joint angles for the Maya-finger and then save the result as an animation keyframes. These keyframes can either be rendered

out as is, or exported to a standard motion format, such as amc/asf, v/vsk, or bvh.

6 Conclusion

This work describes a simple, straight forward mapping of the leap device for estimating hand poses. Our framework directly integrates the Leap Motion controller into Maya to create an intuitive user interface for animating hand motions, as well as for puppeteering other rigged models. Once animated, the poses are easily exported from maya into standard motion formats such as amc/asf, v/vsk, or bvh.

The Leap Motion controller shows a lot of promise for the collection of hand gestures, thanks to its small size, cost, and input capabilities which are tuned to the detection of hands. Thus it has the potential to enable fast, simple hand collection which is difficult using traditional methods.

In this work, we do not evaluate sophisticated methods for dealing with missing finger data or handling unusual poses. This is the natural next step. However, even our simple approach produces very compelling and good results. Our hope is that this work encourages and aids others interested in trying this device.
